Middlebury College

## A Musical Note

Playing a musical note creates regular **vibrations** in the air, which are detected by our auditory systems. **Two questions:**

1. At what **time** does the note happen?
2. What is its **pitch**? (In physics terms: What is the **frequency** of the vibrations, in cycles per second?)

I claim that **neither question has a definite answer:**

1. The note extends over a **range of times** — we could talk about when we reach the start of the note, or the middle, or the end, but there's no **unique** time for the note.
2. This case is more subtle, but actually the pitch has a **completely analogous** ambiguity. The shorter the time for which the note is played, the wider the **range of pitches** are involved.

## Musical Uncertainty

If we play the note for a **short time**, there's a **narrow** range of times involved. So the ambiguity in the time at which the note is played is **small**. But this is precisely when the ambiguity about the pitch is **large** — as you can hear by playing shorter and shorter samples of the same note.

Conversely, if we play the note for a **long time**, there's a **wide** range of times involved. So the ambiguity in the time at which the note is played is **large**. But this is precisely when the ambiguity about the pitch is **small**.

This **uncertainty** can be made mathematically precise:

$$\text{Uncertainty in Time} \times \text{Uncertainty in Pitch} \geq \frac{1}{4\pi}$$

## Internet Uncertainty

We said that a **short** pulse contains a **wide** range of frequencies.

This is why high speed internet (lots of short pulses) requires high **bandwidth**:

**Low** bandwidth version:

Low bandwidth of ordinary telephone is why it's hard to hear the difference between "b" and "v."

## Heisenberg's Uncertainty Principle

In quantum mechanics, the motion of a particle in space works the exact same way.

1. Location of the particle  $\Leftrightarrow$  Time of the note
2. Movement of the particle (momentum)  $\Leftrightarrow$  Pitch of the note

and so ( $h =$  Planck's constant):

$$\text{Uncertainty in Position} \times \text{Uncertainty in Momentum} \geq \frac{h}{4\pi}$$

In quantum mechanics, position and momentum are **not independent**: They are tied together by the relationship between time and frequency.

## Uncertainty and its Consequences

On the scale of everyday life, these uncertainties are **very small**. But for distances at the scale of atoms or semiconductors, they become important.

In particular, if we are uncertain about a particle's motion, we can't be sure it's at rest. **Nothing can stand perfectly still!**

So, for example, **electrons** in a material have to **move around**. That creates regions with **negative** charge, and leaves behind regions with **positive** charge.

But then the opposite charges attract, and try to get closer together. But once they're closer together, their **attraction** is stronger than the **repulsion** of the like charges, creating an **attractive force!**

## A Force From Nothing

In chemistry, these fluctuations appear as [van Der Waals](#) (more precisely, [London dispersion](#)) forces:

## Calculating Fluctuation Forces

In 1948, Hendrik Casimir predicted a quantum-mechanical force between uncharged conducting parallel planes. The first precision verifications did not take place until 1994, however.

Lamoreaux; Mohideen and Roy;

Bressi, Carugno, Onofrio, and Ruoso;

Chan, Aksyuk, Kleiman, Bishop, and Capasso

[Mohideen & Roy 1998]

Until recently, theoretical calculations relied almost exclusively on Casimir's result, approximating everything as parallel planes.

Our goal: Develop a general, systematic, practical method for calculating Casimir forces, appropriate for edges and other surfaces with high curvature.

# Calculational Tools

Our group has worked on **new tools** to calculate Casimir forces for a wider range of situations. **The key idea**: Start from information about how electromagnetic waves (infrared, visible light, ultraviolet) reflect (**classically**) from each object **individually**.

[Emig, Graham, Jaffe, Kardar, Rahi]

We use waves appropriate to the objects' shapes (planar, cylindrical, spherical, etc.) and then **weave together** the reflection data using **geometrical formulae** relating one kind of wave to another. This step encodes the objects' relative **positions and orientations**.

This approach enables us to calculate Casimir forces in a **wide variety** of different situations:

$$T_{M\lambda m}^{\text{cone}} = -\frac{\partial_{\theta_0} P_{i\lambda-1/2}^{-m}(\cos\theta_0)}{\partial_{\theta_0} P_{i\lambda-1/2}^m(-\cos\theta_0)}$$

$$T_{E\lambda m}^{\text{cone}} = -\frac{P_{i\lambda-1/2}^{-m}(\cos\theta_0)}{P_{i\lambda-1/2}^m(-\cos\theta_0)}$$

$$T_{Ghm}^{\text{cone}} = \frac{P_0^{-|m|}(\cos\theta_0)}{P_0^{-|m|}(-\cos\theta_0)}$$

$$T_{M\pm\mu k_z}^{\text{wedge}} = \frac{e^{\mu\theta_0} \mp e^{-\mu\theta_0}}{e^{\mu(\pi-\theta_0)} \mp e^{-\mu(\pi-\theta_0)}}$$

$$T_{E\pm\mu k_z}^{\text{wedge}} = -T_{M\mp\mu k_z}^{\text{wedge}}$$

$$T_{M\mathbf{k}_{\parallel}}^{\text{plate}} = -1 \quad T_{E\mathbf{k}_{\parallel}}^{\text{plate}} = +1$$

$$|\mathbf{E}_P\rangle = \sum_{P'} U_{PP'} |\mathbf{E}_{P'}\rangle$$

$$T_{Mlm}^{\text{sphere}} \quad T_{Elm}^{\text{sphere}} \quad T_{Mmk_z}^{\text{cylinder}} \quad T_{Emk_z}^{\text{cylinder}}$$

## Applications

### Micromechanical devices:

- accelerometers
- piezoelectrics
- pressure sensors
- gyroscopes

are already incorporated in a wide range of technological applications.

[Images from Canadian Assoc. of Road Safety Professionals, Wikipedia]

[Chan 2007]

As these technologies move to smaller and smaller length scales, Casimir forces and other quantum-mechanical effects will become important (for better or worse).

Deviations from the predicted Casimir forces could also allow us to discover new physical laws!

## On to the Cosmos

The “**quantum fluctuations**” that give rise to the Casimir force are also the source of a major unsolved mystery in cosmology.

Because of the uncertainty principle, empty space **can't truly be empty** — that would again imply too much certainty. For example, the **electric and magnetic fields** can't be exactly zero — there's an uncertainty between them as well. But if there are **fluctuations** in empty space, then there should also be **energy** in empty space.

Energy in empty space doesn't affect most physical processes, since **we can't extract it**; it's just always there.

But according to  $E = mc^2$ , a source of energy is also a source of mass. So **gravity** should notice this energy. And it does so in a surprising way.

## Dark Energy

Ordinary matter **slows** the expansion of the universe, since it pulls matter back together. But the energy of empty space, known as **dark energy**, has the opposite effect: It **accelerates** this expansion. The key difference is the **pressure** it produces.

**General relativity** says that both energy ( $= mc^2$ ) and pressure contribute to the force of gravity. But pressure is **three times more important** than energy in three-dimensional space.

The pressure of **ordinary matter** is **very small** on cosmological scales — atoms and molecules need to be moving **close to the speed of light** for their pressure to be important.

## Under (Negative) Pressure

If you let a gas of ordinary matter expand, its energy goes **down**: It does **work**.

The same result holds when the expansion is caused by **the expansion of the universe** instead of a piston.

[Image from WikiPremed]

Dark energy gives a **fixed energy per unit volume** to empty space. So as the universe expands, the volume increases, and the energy goes **up**! (And that's where we think all the energy in the universe originally came from. . . .)

So it's a form of energy with **negative** pressure. That turns out to reverse its effect on the expansion of the universe: Rather than slow the expansion down, dark energy **speeds it up**!

## Dark Energy

Einstein was the first to identify the possibility of dark energy, when he developed the theory of general relativity. But when general relativity turned out to **work just fine** without dark energy, he rejected the possibility, calling it his “**greatest blunder.**”

Later, when the inevitability of **quantum fluctuations** was understood, the mystery returned: The acceleration caused by quantum fluctuations should be more than big enough to **blow the universe apart** before stars, galaxies, etc. could form. So physicists assumed there must be (but couldn't find) some law that prevented quantum fluctuations from contributing to gravity.

But in 1998 a **new experiment** made the situation even more confusing. . . .

## Supernova Redshifts

Supernovae are cataclysmic explosions of dying stars. They are so bright that we can observe them in distant galaxies, and they are “standard candles” in that they have a predictable intrinsic brightness. Comparing this intrinsic brightness to a supernova’s apparent brightness determines its distance, and looking at its redshift determines how fast it is moving away from us.

[Image from Wikipedia]

Seeing supernovae that are so far away enables us to look back in time at earlier stages in the universe’s expansion. Two groups studying distant supernovae found remarkable result: The redshift is too small for galaxies in the past compared to today. So the expansion of the universe has accelerated, driven by dark energy, which fills empty space.

## Quantum Mechanics to the Rescue?

The energy density we observe in dark energy is still **very small** in comparison to what we'd expect from quantum fluctuations. Even in the most optimistic scenario it's still **off by a factor of  $10^{15}$** .

We only notice dark energy because the universe is so **big** (and mostly empty). But it makes up about 73% of the energy in the universe. Which yields another mystery: The amount of energy in other forms of matter is roughly **constant** in time, while the amount of energy in dark energy **grows** as the universe expands.

So **earlier** in the history of the universe, the fraction in dark energy was 0.001%; **later** in the history of the universe, it will be 99.999%.

We live in the **special time** where these numbers are **even close** to 50%. Just a coincidence?

## An Explanation?

A recent but controversial explanation is the **anthropic principle**.

Our current cosmological models can naturally incorporate **multiple universes**, each with their own physical laws. Those universes that have a more “normal” amount of dark energy would get **blown apart** before stars or galaxies could form. So we live in the **rare universe** in which we could exist to ask questions about our universe.

It's also the case that **small changes** in other fundamental constants would make life as we know it impossible (for example, by making nuclei of common elements **unstable**).

But maybe this is just a way of saying that we give up...
